Temporal characteristics of social support in colorectal cancer survivors during the first year post operation

Dongxing Zhang, Yuan You, Zhongmin Zhang
Department of Gastrointestinal Surgery, Gui Zhou Provincial People’s Hospital, Guiyang, 550002, Gui Zhou Province, China

Summary

Purpose: To describe the level of perceived social support and to identify its predictors among Chinese colorectal cancer (CRC) survivors during the first year post operation.

Methods: Newly diagnosed cases of colorectal cancer aged 18 and above who were admitted for curative surgery in a tertiary care hospital between January 2012 and July 2014 were consecutively recruited. This cohort study included 5 assessment waves over the first year post surgery (at baseline, 4-6 week, 3-month, 6-month and 12-month follow-up) regarding social support level among 189 CRC survivors. ANOVA and linear mixed models were applied to determine the change in social support and its predictors using SPSS version 18.0.

Results: Social support level remained relatively stable and high in the first 3 months post surgery, but decreased significantly at 6 months and then remained low afterwards, displaying an overall decreasing trend over time. Females, lower family income, lack of health insurance and advanced clinical disease stage were negatively associated with social support.

Conclusion: These findings suggest that the future intervention programs should commence soon after surgery, despite the fact that they were high before this time point.

Key words: China, colorectal cancer, linear mixed model, perceived social support

Introduction

CRC is one of the most prevalent malignancies worldwide. In China, an estimated 310,244 people were newly diagnosed with CRC in 2011, which accounted for 9.20% of overall new cancer cases [1]. Given the advances in screening technologies and treatment modalities, the overall mortality for CRC has declined in recent years [2]. However, CRC survivors often experience significant physical, emotional, and social changes following the diagnosis, treatment and treatment-related side effects [3,4].

Social support, a multidimensional construct which included emotional, instrumental, and informational aspects [5,6], is widely acknowledged as beneficial to cancer survivors. Previous studies investigating the social support level in cancer survivors were generally consistent to the conclusions that the majority of cancer survivors received high level of social support. In a descriptive study in Iran, Faghani et al. assessed the level of social support in 187 cancer survivors and found that the total score of the multidimensional scale of perceived social support (MSPSS) was 68 and ranged between 7 and 84, indicating that Iranian cancer survivors received high levels of social support and family members were the most important source of this support. Based on a survey of 113 geriatric lung cancer patients who were receiving chemotherapy Jatoi et al. found that the majority of patients reported that they could seek help if they had medication side effects. Fagundes et al. [10] also reported that women who were newly diagnosed with breast cancer received higher levels of social support from family and friends than
women in the benign breast tumors group. However, findings from most of these studies were based on cross-sectional study design and social support was measured at one or two time points only (usually at the time of initial detection and treatment). Up until today, the changes in social support over time among CRC survivors after surgery are not well described. Only few studies reported decline of social support over time during post-treatment follow-up in breast cancer patients [11,12], but prior research provided little empirical evidence about social support in CRC survivors. In addition, although a few demographic and clinical predictors of social support including age, income and race were identified in previous studies [9,15], researchers emphasized the need of more insights about other attributes of social support, so that an appropriate supportive care intervention could be planned and implemented among cancer survivors.

To the best of our knowledge no such study was ever conducted to understand the social support and the associated factors among Chinese CRC survivors. Given the diverse cultural context, different stressful events and level of self-acceptance, the concept of social support varied across regions in cancer patients. Thus, validation and comparison of prior findings about social support across published studies would be less informative and misleading. The lack of information hampered the efforts to suggest effective intervention strategies for this population. The present study was conducted to describe the level of social support and its predictors among Chinese CRC survivors during the first year post operation.

Methods

Study setting and participants

This prospective study was conducted at Gui Zhou Provincial People’s Hospital, Gui Zhou Province, China, between January 2012 and July 2014. Patients were eligible to participate if they were aged 18 or above, permanent urban residents of Gui Zhou Province, China, newly diagnosed with CRC and admitted for corrective surgery during the said period. Patients diagnosed with other cancers or had significant cognitive impairment or any other psychiatric problems that might interfere with communication were excluded. CRC was diagnosed and confirmed by pathologists. All potential subjects were screened and examined by clinicians for eligibility. Written informed consent was obtained from each eligible participant before the interview. Participants were free to withdraw from study any time without any consequences towards their treatment. The study content and procedures were reviewed and approved by the Institutional Ethics Review Board (IERB) of the Gui Zhou Provincial People’s Hospital.

Procedures

A face-to-face interview was conducted by trained nurses through a self-administered structured pretested questionnaire among consenting participants prior to surgical operation. Information was collected on socio-demographic characteristics and other relevant medical history. Individual’s satisfaction with available social support was assessed at this time (T1) through self-administered MSPSS. During one-year follow-up period, additional four waves of assessments on social support were performed at 4-6 weeks (T2), 3 months (T3), 6 months (T4) and 12 months (T5) post-surgery. The majority of CRC patients (85% on average) were assessed through face-to-face interview with prior appointment at the hospital and the rest by telephone contact, which was performed by the same nurses.

Measurements

Clinical and demographic information

Patients’ socio-demographic data included age, gender, marital status, education level, occupation, type of health insurance and monthly income. Clinical information such as the stage of cancer was gathered from the hospital records or directly from the attending physician.

The multidimensional scale of perceived social support (MSPSS)

The MSPSS [16,17], which was developed and validated by Zimet et al. in 1988, was used to measure the extent to which the social support was perceived by an individual. Having good internal and test-retest reliability, along with robust factorial validity, this scale was proven to be reliable and valid in diverse samples [16,17]. It included 12 items with a 7-point likert-type scale, ranging from ‘very strongly disagree’ to ‘very strongly agree’ for each item. A total score was calculated by summing the results for all items. Scores ranged between 12 and 84, where higher scores indicated higher level of perceived social support. In addition, separate subscales could be used by summing the responses from the items in each of the three dimensions: family (Item 3, 4, 8 and 11), friends (Item 6, 7, 9, and 12) and significant others (Item 1, 2, 5, and 10). The possible scores in the subscales ranged from 4 to 28.

Statistics

Statistical analysis was performed using statistical analysis software SPSS, version 18.0 (IBM, Armonk, NY, USA). One-way repeated-measure analysis of variance (ANOVA) was carried out to explore how scores of MSPSS changed over time. Post hoc analysis with Bonferroni’s correction was then used to compare the scores between two adjacent time points. To examine the impact of socio-demographic and clinical factors on social support, longitudinal linear mixed model [18] was employed by putting scores on MSPSS as dependent variable and time as well as other factors as independent variables in the regression equation. In this model, time was analyzed as a regular categorical pre-
dictor with five levels (i.e., five time points: T1, T2, T3, T4 and T5). Socio-demographic and clinical variables were analyzed as time-invariant predictors.

**Results**

Overall 227 CRC survivors eligible for the study were consecutively identified. Of those, 38 (16.7%) patients refused. The reasons for refusal were enquired and it was found that 21 subjects did not want to share their perceptions with others, 5 moved out to other places, and 12 did not disclose the reasons. The participants and the non-participants did not differ with respect to age, gender, marital and socioeconomic status. Of 189 subjects responding to the baseline assessment, 17 declined to participate further in the study and 35 (15.6%) died during follow up. Thus, follow–up data were available for 180 (95.2%), 167 (88.4%), 153 (81.0%) and 137 (72.0%) patients at T2, T3, T4 and T5 time point, respectively.

Demographic and clinical characteristics of the patients are shown in Table 1. The majority of patients were male, with mean age 65.1 years. Most patients were married and near half of them were retired. About one third of the patients were covered by basic medical care. More than half of the patients were diagnosed with stage II or lower CRC.

Table 2 presents the mean score of MSPSS and scores on the three subscales at each time point. The total score remained high and relatively stable through T1 to T3. However, a significant drop in score was observed from T3 to T4, but became stable afterwards. The score on the three subscales, including support from family, friends and significant others, displayed a similar trend to that of the total score, with slight variation from T1 to T3 and T4 to T5 but significant decrease was noted from T3 to T4.

As shown in Table 3, the mixed model analysis indicated a significant effect of time on MSPSS. The mean scores on MSPSS at T4 and T5 were 3.16 and 3.18 points lower than that at T1, respectively. There were no obvious changes of scores on MSPSS at T2 and T3 as compared to T1. Moreover, female CRC survivors reported 1.71 points lower levels of MSPSS than male survivors. The total family income showed a positive association with score on MSPSS over time, with higher score being observed in patients with higher income. Furthermore, compared to those with free medical care or other commercial health insurance, an average of 2.64 points lower level of MSPSS was observed in patients lacking any kind of health insurance or with basic medical care. In addition, patients with disease stage II or below scored 1.37 points higher than those with disease stage III or above. There was no significant association of factors like age, education and marital status with scores on MSPSS.

**Discussion**

In this prospective study we assessed the level of social support and determined the potential predictors during the first year post surgery in a sample of CRC survivors in Chinese population. Our data showed that social support level remained relatively stable and high in the first three months post surgery, but decreased significantly at 6 months and remained low afterwards, displaying an overall decreasing trend over time. Female gender, lower family income, lack of health insurance and higher clinical stage of the disease...
were negatively associated with social support. The findings of the present study probably generated valuable insights about the management and prognosis of CRC survivors in China.

In the present study we observed that CRC patients received higher levels of support just before surgery and the first 3 months post surgery. This was in line with most reports from cancer patients in China. In a cohort questionnaire survey on patients with ovarian malignancies, Zhang et al. reported that 97% of the subjects attained good overall social support during the whole period of chemotherapy [19]. In a recent observational study in patients with esophageal carcinoma [20], the authors indicated that patients reported a high level of support from their family members during the first three months after surgery. The high levels of social support, as these studies indicated [21], has been connected to low levels of anxiety and depression, and thereby, played an important role in facilitating their adaption to cancer diagnosis and treatment.

The level of social support, however, might be transiently higher at the time of initial detection and treatment, and it would experience a natural return to baseline level after an initial boost over time [22]. Consistent to this, we observed in our study an overall decreasing trend during the first year post surgery. Similar findings were also reported by previous prospective studies conducted in other cancer survivors. In a study on women with early stage breast cancer [11], patients reported a persistent decline of perceived social support and satisfaction over time. A study by Thompson et al. [12] also revealed a similar pattern in a consecutive sample of women with breast cancer, where social support was significantly higher at baseline and then declined over time. The levels of social support observed in these studies might provide valuable insights for appropriate interventions among cancer survivors.

Notably, we observed that, six months following definitive surgery (T4), social support showed a significant decline as compared to that at 3 months (T3), and remained relatively stable before T3 and after T4. This suggested that it might be a potentially important time period in which patients seemed particularly vulnerable to experiencing impaired social support. It was, therefore, necessary to identify potential factors that might have led to this outcome. During this time, post-operative complications usually subside and inci-

Social support in colorectal cancer survivors

JBUON 2017; 22(4): 886

sions heal [23]. Therefore, the need for fulltime care and attention from health providers or caregivers seemed less during this phase [24]. Previous reports from clinicians and cancer patients also indicated that several months after surgery, interactions with healthcare personnel and other support providers significantly decreased [25]. In addition, due to the continuing time management pressure and high demand of constant medical care in postsurgery patients, caregivers of these patients, as demonstrated in previous studies [26,27], were at higher risk of developing poor psychosocial and physical outcomes over time. Thus, it was quite difficult for them to provide sustainable high level of support to patients as expected. However, some researches specifically indicated that the availability and quality of social support were associated with patients’ worry about cancer progression and survival [28,29]. Findings from the present study could provide valuable guidance regarding the timing of initiation of an intervention for CRC patients.

In the present study, we found that female gender, lower family income and higher disease stage were negatively associated with social support, which was consistent with previous reports [30]. Moreover, insurance coverage had been shown to be an important factor influencing social support in CRC patients. Patients without health insurance had to pay for the treatment cost by themselves, and the cost could only be partially reimbursed for those covered by basic medical care when they became ill and were admitted to the hospital [31]. This further led to huge financial burden for most families.

Some limitations in the present study should be acknowledged. As participants were selected through a hospital-based nonrandom sampling in a single urban area, they were not representative of all Chinese CRC survivors. So generalization of the study findings to draw conclusion about all CRC survivors is not recommended and any extrapolation of the results beyond the study population should be done with caution. Moreover, in the present study we focused on the social support in CRC survivors and did not have a concurrent control group for comparison. So it remained unclear whether the decline of social support in CRC survivors was of concern. Given the high level at baseline, it was possible that it still remained at higher level compared to individuals without cancer. In addition, we did not examine whether the decline in social support would lead to functional impairment and poor quality life in cancer patients. Future research is needed to provide insights into such associations.

Conclusions

In conclusion, the findings of this study indicated that although CRC survivors received high level of social support at very earlier stage after surgery, they were likely to experience a significant decline at 6 months. Lower family income, lack of health insurance and female gender were negatively associated with social support over time. These findings suggested that the future intervention programs should commence not later than 6 months post surgery, despite the fact that it was high before this time point.

Acknowledgements

The authors would like to express their sincere gratitude to the medical staff at the Department of Gastrointestinal Surgery of Gui Zhou Provincial People’s Hospital for their kind assistance in acquisition of data and field work.
